Funding: The individual centres and collaborators that undertook ISAAC Phase Three were funded by numerous sources throughout the world. Currently, the main source of funding for the ISAAC International Data Centre (IIDC) is The BUPA Foundation. Many New Zealand funding bodies have contributed support for the IIDC during the periods of fieldwork and data compilation (the Health Research Council of New Zealand, the Asthma and Respiratory Foundation of New Zealand, the Child Health Research Foundation, the Hawke’s Bay Medical Research Foundation, the Waikato Medical Research Foundation, Glaxo Wellcome New Zealand, the NZ Lottery Board and Astra Zeneca New Zealand). Glaxo Wellcome International Medical Affairs supported the regional coordination for Phase Three and the IIDC.

Running title: ACETAMINOPHEN AND ASTHMA RISK

Word count: 3,166 (excluding abstract)

Summary: This global study has shown that the reported use of acetaminophen is associated with an exposure-dependent increased risk of the symptoms of asthma, rhinoconjunctivitis and eczema in adolescent children. This association was present in all major regions of the world and persisted in multivariate analyses which controlled for confounding variables. These findings add to the evidence that acetaminophen use in childhood may be an important risk factor for the development and/or maintenance of asthma.

At a glance commentary: Scientific knowledge on the subject: There is epidemiological evidence that exposure to acetaminophen in the intrauterine environment, early childhood and adult life is associated with an increased risk of asthma. The potential mechanisms for these effects of acetaminophen include oxidant-induced airways inflammation and enhanced Th2 responses.

What this study adds to the field: Acetaminophen use may represent an important risk factor for the development and/or maintenance of asthma, rhinoconjunctivitis and eczema in adolescents.

[AJRCCM: ISAAC paracetamol paper 13-14 yr olds final – 21/06/10]
ABSTRACT

Rationale: There is epidemiological evidence that the use of acetaminophen may increase the risk of developing asthma.

Objective: To investigate the risk of asthma and other allergic disorders associated with the current use of acetaminophen in 13 to 14 year old children in different populations worldwide.

Methods: As part of the International Study of Asthma and Allergies in Childhood (ISAAC) Phase Three, 13 to 14 year old children completed written and video questionnaires, obtaining data on current symptoms of asthma, rhinoconjunctivitis and eczema, and a written environmental questionnaire obtaining data on putative risk factors including acetaminophen use in the past 12 months.

Measurements: The primary outcome measure was the odds ratio (OR) of current asthma symptoms associated with acetaminophen use calculated by logistic regression.

Main results: A total of 322,959 adolescent children from 113 centres in 50 countries participated. In the multivariate analyses the recent use of acetaminophen was associated with an exposure-dependent increased risk of current asthma symptoms [OR 1.43 (95% CI 1.33 to 1.53) and 2.51 (95% CI 2.33 to 2.70) for medium and high versus no use respectively]. Acetaminophen use was also associated with an exposure-dependent increased risk of current symptoms of rhinoconjunctivitis and eczema.

Conclusions: Acetaminophen use may represent an important risk factor for the development and/or maintenance of asthma, rhinoconjunctivitis and eczema in adolescent children.

Word count: 220

Key words: Acetaminophen, ISAAC, asthma, rhinoconjunctivitis, eczema
INTRODUCTION

Evidence is accumulating that the use of acetaminophen may raise the risk of developing asthma and that its widespread increasing use over the last 30 years may have contributed to the rising prevalence of asthma in different countries worldwide (1,2). The evidence is based primarily on epidemiological studies which have reported that exposure to acetaminophen in the intrauterine environment (3-7), childhood (6,8,9) and adult life (10-13), is associated with an increased risk of asthma, together with one randomised controlled trial reporting increased rates of hospital visits for asthma in children taking acetaminophen compared with ibuprofen (14). The potential mechanisms for these effects of acetaminophen include oxidant-induced airways inflammation and enhanced Th2 responses (1,2,15).

Recently we have observed from Phase Three of the International Study of Asthma and Allergies in Childhood (ISAAC) that the reported use of acetaminophen in the first year of life was associated with an increased risk of current asthma symptoms in 6 to 7 year old children (9). Recent acetaminophen use was also associated with a dose-dependent increased risk of current asthma symptoms in the 6 to 7 year old children. ISAAC Phase Three also surveyed 13 to 14 year old children, which provided the opportunity of examining whether the associations between acetaminophen use and asthma in young children extended to adolescent children. In this manuscript we report the findings from these analyses.
METHODS

ISAAC Phase Three is a multi-centre, multi-country, cross-sectional study of two age groups of schoolchildren (6 to 7 year olds and 13 to 14 year olds) chosen from a random sample of schools in defined geographical areas within each centre (16,17). The data for the 13 to 14 year old children (referred to in this manuscript as adolescents) are presented in this manuscript. The study instruments were two written questionnaires and a video questionnaire which were completed by the adolescent. The first written questionnaire (prevalence) obtained data on demographic characteristics and on asthma, rhinoconjunctivitis and eczema symptoms. The second written questionnaire (environmental) obtained data on a wide range of putative protective and risk factors for the development of asthma and allergic disorders. The written questionnaires were translated into the local language with back-translation into English (18). The video questionnaire showed different audiovisual scenes of clinical asthma. The complete written questionnaires and information concerning the video questionnaire can be found on the ISAAC website – http://isaac.auckland.ac.nz.

The question relating to acetaminophen use was:

“In the past 12 months, how often on average have you taken paracetamol (e.g. Panadol, Pamol)?” Never/At least once a year/At least once per month.

Adolescents in the 1+ per year (medium) and 1+ per month (high) categories were compared to those in the “never” category.

A participant was considered to have current asthma symptoms (current wheeze) if they provided a positive response to the written question “Have you had wheezing or whistling in the chest in the past 12 months?”

A participant was considered to have current symptoms of rhinoconjunctivitis if they provided positive responses to both these written questions:
“In the past 12 months have you had a problem with sneezing or a runny or blocked nose when you DID NOT have a cold or the flu?” If yes, “In the past 12 months has this nose problem been accompanied by itchy watery eyes?”

A participant was considered to have current symptoms of eczema if they provided positive responses to both these written questions:

“Have you ever had this itchy rash at any time in the past 12 months?” If yes, “Has this itchy rash at any time affected any of the following places – the folds of the elbows, behind the knees, in front of the ankles, under the buttocks, or around the neck, ears or eyes?” (These questions were preceded by the question “Have you ever had an itchy skin rash which was coming and going for at least 6 months?”)

Symptoms of severe asthma were defined by the responses to the following written questions:

(1) “How many attacks of wheezing have you had in the past 12 months?” None/1 to 3/4 to 12/More than 12. Participants who reported 4 or more attacks were considered to have symptoms of severe asthma.

(2) “In the past 12 months how often, on average, has your sleep been disturbed due to wheezing?” Never woken with wheezing/Less than one night per week/One or more nights per week. A response of 1 or more nights per week was considered to indicate symptoms of severe asthma.

(3) “In the past 12 months, has the wheezing ever been severe enough to limit your speech to only one or two words at a time between breaths?” Yes/No. A positive response was considered to indicate symptoms of severe asthma.

For the video questionnaire, participants viewed five scenes of clinical asthma and were asked to indicate whether they had experienced similar symptoms “ever”, if yes, “in the past year”.

A participant was considered to have current wheeze (video) if they provided a positive response “in the past year” to the first scene, showing a person wheezing at rest.
Adherence to the protocol was assessed by the ISAAC International Data Centre and centres with serious discrepancies were excluded.

**Analysis**

To be included in the analysis, centres were required to have studied at least 1000 children and have a response rate of >70%. Odds ratios (ORs) were calculated using generalised linear mixed models with a binomial distribution and logit link and with centres being modelled as a random effect. The analyses on all study participants were adjusted for sex, region of the world, language and gross national income as previously described (9).

Multivariate analyses were conducted to investigate whether the association between symptoms and acetaminophen use were confounded by other variables in the environmental questionnaire. For inclusion in these analyses, centres were required to have at least 70% data available for all covariates; subjects who had a missing value for any of the covariates were removed. The covariates included in the multivariate analyses were maternal education, current maternal smoking, siblings, current consumption of vegetables and fruit as previously described.

The primary outcome measure was the association between current acetaminophen use and current asthma symptoms, expressed as the odds ratios (medium versus none, high versus none), as determined by multivariate analysis.

Conditional analyses were also undertaken in which the odds ratios were calculated, for the risk of rhinoconjunctivitis or eczema, associated with acetaminophen use, in those who did not report wheezing in the past 12 months.
The population attributable risk of current symptoms due to each acetaminophen use measure was calculated using the Mantel-Haenszel approach using the adjusted relative risk and the proportion of the participants who were exposed. This calculation method makes the ‘homogeneity’ assumption (19).

All analyses were carried out using SAS version 9.1 (SAS Institute, Inc., Cary, NC, USA).

**Ethics approval**

All participating centres obtained local ethics approval.

**The role of the funding sources**

The funders of the study had no role in study design; in the collection, analysis, and interpretation of data; in writing of the report; or in the decision to submit the paper for publication.
RESULTS

There were 361,598 13 to 14 year old adolescents from 122 centres in 54 countries who completed the Phase Three environmental questionnaire (Figure 1). Nine centres were excluded because they did not include the acetaminophen question or had <70% data for current acetaminophen use. Participants with missing data for gender or current acetaminophen use were excluded at this stage. These exclusions resulted in 322,959 adolescents from 113 centres in 50 countries contributing data to the analyses presented. Following the exclusion of centres in which there was <70% data for any covariate, and of participants for whom there was missing data for any covariate, there were 180,887 adolescents from 77 centres in 36 countries included in the multivariate analyses.

The mean percentage of children exposed to acetaminophen at least once a month was 30%, with levels ranging from 2% in Taiwan to 68% in Nigeria (Figure 2a). The mean percentage of children exposed to acetaminophen at least once in the previous 12 month period was 73%, ranging from 41% in China and 92% in Panama.

Asthma

The reported use of acetaminophen in the past 12 months was associated with a significant exposure-dependent increased risk of current asthma symptoms (Table 1). In the adjusted analyses, the odds ratios for current asthma symptoms for medium (1+ per year) and high (1+ per month) acetaminophen use compared with no use were 1.38 (95% CI 1.31 to 1.46) and 2.36 (95% CI 2.24 to 2.50) respectively. In the multivariate analyses the odds ratios for current asthma symptoms for medium and high acetaminophen use compared with no use were 1.43 (95% CI 1.33 to 1.53) and 2.51 (95% CI 2.33 to 2.70) respectively. The exposure-dependent increased risk of current asthma symptoms with acetaminophen use was present...
throughout the major regions of the world (Table 2, Figure 2). The population attributable risk for asthma symptoms associated with current acetaminophen use was 41%.

The reported current use of acetaminophen was associated with a significant exposure-dependent increased risk of current wheeze (video) (Table 1, Figure 2). The magnitude of the increased risks of current wheeze (video) and symptoms of severe asthma were similar to those for current wheeze. The population attributable risk for symptoms of severe asthma due to current acetaminophen use was 43%.

**Rhinoconjunctivitis and eczema**

The reported use of acetaminophen in the past 12 months was associated with a significant dose-dependent increased risk of current symptoms of rhinoconjunctivitis and eczema (Table 3). The risk was observed in most regions of the world (Table 4, Figure 3). The population attributable risk for current symptoms of rhinoconjunctivitis and eczema, associated with current acetaminophen use was 36% and 40% respectively.

When participants with current wheeze were excluded from the multivariate analysis, the use of acetaminophen was associated with a significantly increased risk of current symptoms of rhinoconjunctivitis with odds ratios of 1.33 (95% CI 1.25 to 1.42) and 2.18 (95% CI 2.04 to 2.33) for medium and high acetaminophen use respectively. Likewise, when participants with current wheeze were excluded from the analysis, there was an increased risk of current symptoms of eczema associated with the use of acetaminophen with odds ratios of 1.32 (95% CI 1.21 to 1.44) and 1.87 (95% CI 1.7 to 2.05) for medium and high acetaminophen use respectively. Similar estimates of risk were observed when participants with asthma ever
were excluded from the multivariate analysis, for both current symptoms of rhinoconjunctivitis and symptoms of eczema (Online Supplement).
DISCUSSION

This study has identified that the reported use of acetaminophen in 13 to 14 year old adolescent children was associated with an exposure-dependent increased risk of asthma symptoms. The association was present in all major regions of the world and persisted in the multivariate analyses which controlled for confounding variables. The magnitude of the association was substantial with a 2.5-fold increased risk associated with frequent acetaminophen use, at least once per month. Similar magnitudes of risk were observed with symptoms of severe asthma determined by written questionnaire and with current wheeze when assessed by video questionnaire, both measures of clinically significant asthma (20-23). The public health significance of the findings is suggested by the population attributable risk for symptoms of severe asthma due to acetaminophen of 43%. Significant associations were also observed between current acetaminophen use and the risk of the related conditions rhinoconjunctivitis and eczema.

These findings extend our previous observations from ISAAC Phase Three, that the use of acetaminophen in infancy and current use was associated with an increased risk of asthma symptoms in 6 to 7 year old children. While many of the methodological issues relating to the earlier study also apply to analyses in the 13 to 14 year old age group, there are also some differences which are relevant to the interpretation of the study findings. Firstly, the current study had greater power and worldwide representation, with around 320,000 adolescents from 113 centres in 50 countries, compared with around 200,000 6 to 7 year old children from 73 centres in 31 countries. Secondly, we utilised a video questionnaire in which the audiovisual presentation of clinical asthma in different situations was presented. Validation studies have shown that the video questionnaire has high sensitivity and specificity for identifying children
with bronchial hyperresponsiveness, providing data relatively free from bias due to language and culture (20-22).

Confounding by indication represented the most important consideration in the interpretation of the primary 6 to 7 year old ISAAC study findings of acetaminophen use in infancy (24-27). Indeed, since publication of the earlier ISAAC findings, there have been a number of reports from prospective cohort studies that the association between acetaminophen use in early life and the risk of asthma in later childhood could be explained by confounding, due to the close association between acetaminophen use and respiratory morbidity in early childhood (28-30). While such confounding is less likely to be relevant to the current use of acetaminophen in adolescent children, it may still be present to some extent. Another possibility is that there could be confounding by reverse causation if adolescents with asthma were more likely to develop febrile illnesses or experience pain, and as a result have greater acetaminophen use than non-affected adolescents. There does not appear to be data to assess this proposition for the wide range of febrile illnesses affecting adolescents worldwide although those with asthma may be more prone to migraine for which acetaminophen may be prescribed (31). However, there is evidence that acetaminophen may cause greater nasal symptoms and signs, and a reduced serum neutralising antibody response when taken for rhinovirus infection (32). This observation is relevant both to our study findings, and consideration of the nature of the association between acetaminophen use for respiratory tract infections in infancy and development of asthma in later childhood.

Another consideration is that in many countries, acetaminophen is marketed as the preferred analgesic and antipyretic of choice in persons with asthma. Although this has the potential to result in preferential use of acetaminophen, the observation that the association was present in populations with widely differing lifestyles, standard of living, medical practice and
availability of information of over-the-counter products containing acetaminophen suggests that it may not have had a major contribution to the association observed.

It is likely that adolescents who frequently took acetaminophen were more likely to have received acetaminophen in earlier childhood and the risk of asthma may have been due to this earlier use. This cannot be assessed in our study as only information on current use of acetaminophen was obtained, although it is relevant that in the previous ISAAC analysis the risk of current use of acetaminophen in 6 to 7 year old children existed independently of acetaminophen use in the first year of life, and vice versa.

Potential confounding by factors that influence the risk of developing childhood asthma and use of acetaminophen is inherent in cross-sectional population-based studies. To address this issue, the odds ratios were adjusted for centre level factors such as region of the world, language and gross national income, and multivariate analyses were undertaken in which potential confounding factors at the individual level were controlled for. In the multivariate analyses, there was no reduction in the strength of the association between acetaminophen use and asthma, suggesting that there was no major confounding by these factors. This pattern differs from that observed in the analyses from the 6 to 7 year old children, in which the strength of the association was reduced in multivariate analyses, suggesting that confounding was present.

With these considerations in mind we propose that the findings are consistent with the cross-sectional and longitudinal epidemiological studies which have reported that acetaminophen exposure in the intrauterine environment, throughout childhood, and in adult life is associated with an increased risk of asthma (1-16). The findings are also consistent with the one randomised controlled trial of acetaminophen use in asthmatic children (14). In that study,
asthmatic children were randomly assigned to receive either acetaminophen or ibuprofen during a febrile illness. Children randomised to acetaminophen had an increased risk of an outpatient visit for asthma, an effect which was observed for the treatment of fever due to respiratory but not other infective causes. However, as the study did not include a placebo treatment it was not possible to determine whether the observed difference in morbidity was attributable to an increased risk with acetaminophen treatment or a decreased risk with ibuprofen.

Our findings complement the international ecological analyses based on data from countries that participated in ISAAC Phase One and the European Community Respiratory Health Survey in which a positive association between per capita consumption and acetaminophen and the prevalence of asthma in children and adults respectively was reported (33). An observation from these studies is that English-speaking countries, which have amongst the highest prevalence rates of asthma, also have amongst the highest acetaminophen use, suggesting that greater acetaminophen use may explain to some extent the higher prevalence of asthma in English-speaking countries.

Overall, the population attributable risks for current symptoms of asthma and symptoms of severe asthma were around 40%, suggesting that if the associations were causal, they would be of major public health significance. These compare with the population attributable risks of around 30% in the previous ISAAC study of 6 to 7 year old children.

Similar to the findings in 6 to 7 year old children we observed an association between current acetaminophen use and current rhinoconjunctivitis and eczema symptoms in 13 to 14 year old adolescents, and that this association was independent of the presence of asthma. These observations suggest that acetaminophen may have systemic inflammatory effects, possibly
through increasing oxygen stress resulting from depletion of glutathione-dependent enzymes, which may also lead to enhanced TH2 allergic immune responses (1,2,15). Both mechanisms could lead to greater allergic inflammation, resulting in the development or worsening of pre-existing asthma, rhinoconjunctivitis or eczema, depending on the organ systems affected. Furthermore, acetaminophen may suppress the immune response to, and prolong the symptomatic illness from rhinovirus infections (32), which are a common cause of severe exacerbations of asthma in childhood (34), and adult life (35), and in infancy are associated with an increased risk of subsequent asthma (36). Similarly, a recent study of prophylactic acetaminophen given at the time of vaccination illustrates that acetaminophen in routine antipyretic doses is capable of modulating immune responses (37).

In conclusion, the study findings add to the evidence that acetaminophen use in childhood may be an important risk factor for the development and/or maintenance of asthma. However, it is not possible in a study of this design to determine whether the positive association observed was causal. As a result, randomised controlled trials are now urgently required to investigate this relationship further and to guide the use of antipyretics, not only in children, but also in pregnancy and adult life.

Current acetaminophen use: high – 1+/month in past 12 months; medium – 1+ in past 12 months; never – none in past 12 months.

Current wheeze: wheeze in the past 12 months (written questionnaire).

Current wheeze (video): wheeze in the past 12 months (video questionnaire).

Severe asthma symptoms: sleep disturbed due to wheezing on average 1 or more nights per week, or wheezing severe enough to limit speech, or 4 or more attacks of wheezing in the past 12 months.

Adjusted analysis.

* Adjusted for sex, region of the world, language and gross national income. A total of 322,959 children were included from 113 centres in 50 countries. For current wheeze (video), a total of 253,280 children were included from 89 centres in 37 countries.

# Adjusted for sex, region of the world, language and gross national income. Analysis restricted to the centres included in the multivariate analyses.

† Multivariate analysis including centres with at least 70% data available for all covariates. All children who had a missing value for any of the covariates have been removed. Covariates included maternal education, maternal smoking, current diet, siblings. A total of 180,887 children were included from 77 centres in 36 countries. For current wheeze (video), a total of 140,059 children were included from 60 centres in 28 countries.

FIGURE LEGENDS

Figure 1:
Flow diagram of inclusion of children, centres and countries.

Figure 2:
Plot showing the odds ratios for the association between the reported use of acetaminophen in the past 12 months (at least once a month versus none) and current wheeze (A), current wheeze (video) (B), and severe asthma symptoms (C) in 13 to 14 year old children. The dots (●) represent the odds ratios for each of the 77 centres in 36 countries; the square (■) represents the global odds ratio. For every country, the percentage of children exposed to acetaminophen (at least once a month) is stated in brackets.

Figure 3:
Plot showing the odds ratios for the association between the reported use of acetaminophen in the past 12 months (at least once a month versus none) and current symptoms of rhinoconjunctivitis (A) and eczema (B) in 13 to 14 year old children. The dots (●) represent the odds ratios for each of the 77 centres in 36 countries; the square (■) represents the global odds ratio. For each country, the percentage of children exposed to acetaminophen (at least once a month) is stated in brackets.

When participants with asthma ever were excluded from the analysis, the use of acetaminophen was associated with a significantly increased risk of current symptoms of rhinoconjunctivitis with odds ratios of 1.35 (95% CI 1.26 to 1.45) and 2.29 (95% CI 2.13 to 2.47) for medium and high acetaminophen use respectively. Likewise, when participants with asthma ever were excluded from the analysis, there was an increased risk of current symptoms of eczema associated with the use of acetaminophen with odds ratios of 1.3 (95% CI 1.19 to 1.42) and 1.91 (95% CI 1.74 to 2.09) for medium and high acetaminophen use respectively.
